ABSTRACT

We present the results of a multisite photometric observing campaign on the rapidly oscillating Ap (roAp) star 2MASS 16400299-0737293 (J1640; $V = 12.7$). We analyse photometric B data to show the star pulsates at a frequency of 151.93 d^{-1} ($1758.45 \mu\text{Hz}$; $P = 9.5 \text{ min}$) with a peak-to-peak amplitude of 20.68 mmag, making it one of the highest amplitude roAp stars. No further pulsation modes are detected. The stellar rotation period is measured at $3.6747 \pm 0.0005 \text{ d}$, and we show that rotational modulation due to spots is in antiphase between broad-band and B observations. Analysis and modelling of the pulsation reveals this star to be pulsating in a distorted quadrupole mode, but with a strong spherically symmetric component. The pulsational phase variation in this star is suppressed, leading to the conclusion that the contribution of $\ell > 2$ components dictate the shape of phase variations in roAp stars that pulsate in quadrupole modes. This is only the fourth time such a strong pulsation phase suppression has been observed, leading us to question the mechanisms at work in these stars. We classify J1640 as an A7 Vp SrEu(Cr) star through analysis of classification resolution spectra.

Key words: asteroseismology – techniques: photometric – stars: chemically peculiar – stars: individual: J1640 – stars: magnetic field – stars: oscillations.

1 INTRODUCTION

There exists a group of chemically peculiar A stars, known as Ap stars, that show overabundances of elements such as La, Pr, Eu, Sr, Cr, and Nd in their atmospheres, when compared to their ‘normal’ A-star counterparts; in some cases, these elements can be overabundant up to one million times the solar value (Ryabchikova et al. 2004). Often, these abundance anomalies form surface spots that modulate the observed flux of the star as it rotates. The peculiarities in the Ap stars arise from chemical stratification in the presence of a strong, global, magnetic field, which suppresses convection and allows radiative levitation. The magnetic field strengths in Ap stars are often in the range of a few kG, but can be as high as about 30 kG (Babcock 1960; Elkin et al. 2010). It is common to find the magnetic axis misaligned with the rotation axis in Ap stars, leading

to the oblique rotator model (Stibbs 1950). In general, as a result of magnetic braking, the Ap stars are much slower rotators than their non- (or weakly) magnetic counterparts (Stepień 2000; Abt & Morrell 1995); some of them are so strongly braked that their rotation periods can be decades, or even centuries (Mathys 2015).

A subset of the Ap stars is known to show short-period variability, on the order of 5–24 min. These are the rapidly oscillating Ap (roAp) stars. Since their discovery by Kurtz (1982), only 61 roAp stars have been discussed in the literature (for a catalogue see Smalley et al. 2015; Joshi et al. 2016). The driving mechanism of the pulsations in the roAp stars is thought to be the κ -mechanism acting in the H I ionization zone (e.g. Balmforth et al. 2001; Saio 2005), which results in high-overtone pressure modes (p modes) being excited. However, this mechanism cannot explain all the pulsations observed in roAp stars. Rather, Cunha et al. (2013) suggested that some observed modes may be excited by turbulent pressure in the convective zone. Furthermore, there is a subset of roAp stars that seem to pulsate with frequencies much higher than expected – higher than the acoustic

* E-mail: dlholdsworth@uclan.ac.uk

cut-off frequency. Work by e.g. Kurtz et al. (1994b, 2005); Sachkov et al. (2008); Balona et al. (2013); Holdsworth et al. (2016, 2018) has identified these stars, with some authors postulating whether there is yet another driving mechanism at work.

Since the first observations of the roAp stars (Kurtz 1982), it was clear that a relation existed between the pulsation amplitude (and phase) and the rotation period of the star. This led to the development of, and later enhancement of, the oblique pulsator model (Kurtz 1982; Dziembowski & Goode 1985; Shibahashi & Saio 1985a,b; Shibahashi & Takata 1993; Takata & Shibahashi 1994, 1995; Bigot & Dziembowski 2002; Bigot & Kurtz 2011). In this model, the pulsation axis is misaligned with the rotation one, but closely aligned to the magnetic axis. Such a configuration means that the viewing aspect of the pulsation mode changes over the rotation cycle of the star, leading to the observed amplitude and phase modulations. This property of the roAp stars can provide constraints on the geometry of observed pulsations.

Most roAp stars have been discovered through photometric campaigns targeting known Ap stars (e.g. Martinez, Kurtz & Kauffmann 1991; Handler & Paunzen 1999; Dorokhova & Dorokhov 2005; Paunzen et al. 2015), with some later additions through the use of high-resolution, time-resolved spectroscopy (e.g. Hatzes & Mkrtychian 2004; Elkin et al. 2011; Kochukhov et al. 2013). In more recent years, the use of ground-based surveys (Holdsworth et al. 2014a; Holdsworth 2015) and the *Kepler* space telescope (e.g. Balona et al. 2011; Kurtz et al. 2011; Smalley et al. 2015) have yielded new results. However, issues with using ground-based surveys are the sparsity and low-precision of the data. This method is useful for identifying pulsating Ap stars, but precise, high-cadence, follow-up observations are needed to fully study the targets.

The subject of this paper, J1640 (α : 16:40:02.99, δ : -07:37:29.7; 2MASS J16400299-0737293; $V = 12.7$), was first shown to be a roAp star by Holdsworth et al. (2014a) after searching the SuperWASP archive for periodic A star variables. Their results show variability at 151.93 d^{-1} ($1758.45 \mu\text{Hz}$; $P = 9.5 \text{ min}$) with a semi-amplitude of 3.52 mmag in the SuperWASP broad-band filter. With such a high-amplitude pulsation, we consider whether J1640 is similar to the other roAp stars which exhibit similar pulsation amplitudes. Most pulsation amplitudes of roAp stars are below about 10 mmag (Joshi et al. 2016), thus making the subset of high-amplitude pulsators interesting in their own right. Furthermore, these stars KIC 7582608, HD 24355, and J1940 (Holdsworth et al. 2014b, 2016, 2018), are all single mode, distorted quadrupole pulsators which show suppressed pulsation phase variations, meaning that the pulsation cannot be modelled by a single spherical harmonic. These stars require energy from higher ℓ terms to accurately model the phase variations. As J1640 shows many similarities with these stars, we aim to test whether it also belongs to this abnormal group of roAp stars, and thus provide a larger subset of stars to investigate the pulsation driving mechanism in these peculiar class members.

In this paper, we provide a detailed analysis of the WASP discovery data, along with newly obtained, multisite, ground-based observations. Finally, we apply theoretical modelling to the data to better understand this pulsating star.

2 CLASSIFICATION SPECTROSCOPY

To classify J1640, we have spectroscopically observed the star with two different instruments. The first spectrum was obtained with

Table 1. Log of spectroscopic observations of J1640. The DER_SNR code (Stoeck et al. 2008) was used to find the S/N. The rotation phase has been calculated from equation (1). BJD is the mid-point of the exposure, given as BJD-2 450 000.

Instrument	BJD	Integration time (s)	S/N	Resolution (Å)	Rotation phase
WHT/ISIS	6 326.769 9	1200	100	0.86	0.32 ± 0.03
SALT/RSS	6 374.568 8	600	70	0.37	0.06 ± 0.03

Figure 1. Spectra of J1640 (second and third) compared to MK standard stars as labeled. The target spectra have been reduced to the resolution of the standards (i.e. 1.67 Å).

the Intermediate dispersion Spectrograph and Imaging System¹ (ISIS) mounted on the William Herschel Telescope (WHT). The second was obtained with the Robert Stobie Spectrograph (RSS; Kobulnicky et al. 2003) mounted on the Southern African Large Telescope (SALT). We provide a log of the spectral observations in Table 1.

We present the two spectra in Fig. 1 along with three MK standard stars² for spectral classification. We determine that the Balmer lines of J1640 are best represented by the A7 standard. However, the metal lines of J1640 do not match those of the standard star, as is expected

¹ <http://www.ing.iac.es/Astronomy/instruments/isis/>

² Standard star spectra from R.O. Gray's website: <http://stellar.phys.appstate.edu/Standards/>.

in an Ap star. In particular, lines of Sr II at 4077 and 4216 Å are enhanced, Eu II at 4130 Å is also stronger than the standard, as is the line at 4205 Å. There is a weak signature of Cr II at 4111 Å, on the red side of the H δ core. These deviations allow us to conclude that J1640 is an A7 Vp SrEu(Cr) star. Additionally, we note a weak Mg II 4481 Å line when compared to the standard, as well as the commonly observed weak Ca II K line, a trait of Ap stars. Finally, there are slight line strength variations of some of the lines, most notably the Sr II lines, between the two spectra of J1640. This is a result of the difference in rotation phase at which the two spectra were obtained.

To estimate the temperature of J1640, we produce model spectra at a fixed $\log g = 4.0$ (cgs) with the UCLSYN code (Smith & Dworetzky 1988; Smith 1992; Smalley, Smith & Dworetzky 2001) and the VALD 2014 atomic line list, and try to best fit the Balmer lines. Our low-resolution data do not allow for the determination of $\log g$, thus we fix it at this reasonable value. We derive a temperature of 7600 ± 200 K, and show the fit in Fig. 2. The cores of the hydrogen Balmer lines are not fitted well by the model. This is a known problem with LTE models which underpredict the depth of strong lines that are formed high in the atmosphere and subject to non-LTE effects (Gray 2008; Smalley 2014). Coupled with this, the so-called core-wing anomaly is observed in Ap stars (Cowley et al. 2001; Kochukhov, Bagnulo & Barklem 2002). In that case, however, the cores of hydrogen lines are deeper than models, which is not the case here. The underlying cause of the core-wing anomaly is elemental stratification, which leads to non-standard temperature gradients in Ap stars. Hence, in our fits we have ignored the cores of the Balmer lines. Also note in Fig. 2 how weak the Ca K line is with respect to the model. As mentioned earlier, this is a common trait of Ap stars.

To determine the rotation phases at which the spectra were observed, we use the first rotational light maximum in the WASP data as the zero-point, and the rotation period derived in Section 3.2.1, such that:

$$\phi(E) = (2\,455\,334.4160 \pm 0.0009) + (3^d 674.7 \pm 0^d 000.5) \times E, \quad (1)$$

where E is the number of rotation cycles elapsed since the zero-point. The calculated rotation phases are shown in Table 1.

3 PHOTOMETRIC OBSERVATIONS

We present the original SuperWASP discovery data here, from Holdsworth et al. (2014a), with a more in-depth discussion and analysis than previously provided. Furthermore, we present new ground-based data obtained with the 1.0-m and 1.9-m telescopes of the South African Astronomical Observatory (SAAO), and the Las Cumbres Observatory (LCO; Brown et al. 2013) 1.0-m telescope network sited at the Siding Springs Observatory (SSO), Australia, and the Cerro Tololo Interamerican Observatory (CTIO), Chile.

3.1 SuperWASP data

SuperWASP is a leading ground-based project in the search for transiting exoplanets. It also produces excellent data for the study of stellar variability. For full details of the SuperWASP project, see Pollacco et al. (2006); for example of stellar variability studies that have been conducted with the data, we refer the reader to the following papers: Maxted et al. (2008), Thomas et al. (2010), Norton et al. (2011), Norton et al. (2016), Smalley et al. (2011), Smalley et al. (2014), Smalley et al. (2017), Holdsworth et al. (2014a),

Figure 2. The Balmer lines of J1640 (red) compared to a model spectrum of $T_{\text{eff}} = 7600$ K, $\log g = 4.0$ and solar metallicity (black solid line) to determine the effective temperature. Spectra with ± 200 K are plotted with dotted lines to represent the error on the fit. Note the strong line of Sr II in the blue wing of H δ , and Eu II in the red wing. The wavelength is given relative to the core of each Hydrogen line.

Holdsworth et al. (2017), Bowman, Holdsworth & Kurtz (2015), and Greer et al. (2017).

SuperWASP observed J1640 over 3 yr, 2010, 2011, and 2012. Standard data processing is applied to the data on ingest to the archive. On retrieval of the data, outlying points are discarded using a resistant mean algorithm. This process serves to minimize the noise of the amplitude spectrum (see Holdsworth et al. 2014a for an example and details). The final light curve which we present here consists of 20 567 data points. Details of the WASP observations, and frequency analysis, are shown in Table 2.

The 3 yr of SuperWASP observations provide us with a suitably long duration with which to measure the rotation period of the star. To that end, we combine all WASP data and calculate

Table 2. Log of the WASP observations and frequency analysis results. BJD is the start time of the observations, given as BJD-245 0000.0. A non-linear least-squares fit was used to determine the frequencies and amplitudes.

Year	BJD	Length (d)	Number of points	Frequency (d^{-1})	Amplitude (mmag)
2010	5332.370 1	93.023 4	8 474	$151.934 3 \pm 0.000 5$	3.63 ± 0.32
2011	5647.496 1	146.882 3	6 803	$151.934 8 \pm 0.000 4$	3.32 ± 0.40
2012	6012.499 0	94.899 9	5 290	$151.933 8 \pm 0.000 7$	3.83 ± 0.47

Figure 3. Top: low-frequency amplitude spectrum of the WASP light curve showing the rotation frequency of J1640, as well as the $+1 \text{ d}^{-1}$ alias of the negative component. Bottom: the WASP light curve folded on the rotation frequency, i.e. $\nu = 0.272 09 \text{ d}^{-1}$. The data are singly periodic with a period of $1/\nu = 3.675 3 \text{ d}$. The data have been binned 50:1.

the Fourier transform to 1 d^{-1} . We find the dominant peak in the amplitude spectrum at $0.272 09 \pm 0.000 04 \text{ d}^{-1}$, equivalent to a period of $3.675 3 \pm 0.000 5 \text{ d}$. The frequency error quoted here is the formal error in the least squares-fitting, as calculated following Montgomery & O'Donoghue (1999). However, as the authors discuss, formal frequency errors calculated in the presence of correlated ‘pink’ noise in the data can be unrealistically low as (a) the calculation assumes white noise and (b) the frequency error is proportional to the amplitude error. Therefore, by comparing the noise levels (i.e. amplitude error) in the amplitude spectrum at high frequencies – where the noise is white – and at the low frequency of the rotation signal, we can correct for the underestimation in the frequency error at low frequency. In doing so, we find that the real error in frequency is a factor of 1.48 higher than the formal error. Therefore, the rotation period is determined to be $3.675 3 \pm 0.000 8 \text{ d}$. We detect no harmonics of the rotation period in the WASP data. The amplitude spectrum and phase folded light curve of all WASP data are shown in Fig. 3.

To analyse the high-frequency variations in the WASP data, we pre-whiten each individual year in the frequency range $0\text{--}10 \text{ d}^{-1}$ to the noise level in the frequency range around the pulsation. This

Figure 4. Amplitude spectrum of all WASP data. Low-frequency signals have been removed between 0 and 10 d^{-1} . The structure surrounding the pulsation signature is a result of daily aliases.

procedure removes the rotation signature as well as any remaining systematic noise that is not fully removed by the SuperWASP pipeline. We then calculate the frequency and amplitude of the pulsation, fit the results using non-linear least-squares with the results show in the last two columns in Table 2. The frequencies and amplitudes are all in agreement, within the errors, over the 3 yr of observations; the pulsation is apparent at a frequency of 151.934 d^{-1} with an average (weighted) amplitude of 3.58 mmag . Fig. 4 shows an amplitude spectrum of all the WASP data combined.

We can extract no further information from the WASP data as the noise dominates over any sidelobes of the pulsation, or further, low-amplitude, pulsations.

The amplitudes presented in this section are those observed with the SuperWASP broad-band filter (i.e. $4000\text{--}7000 \text{ \AA}$). Observations of the roAp stars are typically made with *B* filters where the pulsational signal-to-noise ratio is greatest. The amplitude reduction in the SuperWASP filter is expected to be of the order 2.3 following the comparison of WASP and *B* data of the roAp star J1940 (Holdsworth et al. 2018), demonstrating that J1640 is one of the highest amplitude roAp stars yet observed.

3.2 Follow-up observations

J1640 was observed as a secondary target at the SAAO during 2016 June. Observations were made with the Sutherland High Speed Optical Cameras (SHOC; Coppejans et al. 2013) mounted on both the 1.0-m and 1.9-m telescopes. We used a Johnson *B* filter for all observations. Integration times were either 5 or 10 s with a readout time of 6.7 ms. Table 3 shows a log of the observations.

Subsequently, the star was observed in 2017 May, June, and July, again with the 1.0-m SAAO telescope, as well as with the LCO 1.0-m telescope network located in Chile and Australia, also through a *B* filter. These facilities are listed as CTIO and SSO in Table 3, respectively.

The SAAO data are reduced using a customized pipeline in PYTHON. Each data cube (typically 1 h long) consists of 360 image frames each with a 10 s exposure time and 6.7 ms readout time. Each image frame is bias corrected and normalized by a flat-field. Aperture photometry is performed using optimized elliptical apertures determined from growth curves of total aperture flux versus aperture area, which capture changing values of FWHM for each source caused by variable seeing. An aperture with the same area as the target star aperture is placed nearby on the CCD, where no sources are present, to determine and subtract the sky background. This is also performed for the comparison star. Time stamps from the

Figure 5. SAAO and LCO phased light curve folded on the rotation period, i.e. 3.6747 d. The plot shows a clear sinusoidal signature. The data have been binned 50:1. Note that the variation is in antiphase with the white-light WASP observations.

original FITS headers are converted to Barycentric Dynamical Time (TDB) and expressed in Barycentric Julian Date (BJD-2 450 000.0).

The LCO data are provided as fully reduced data using their in-house pipeline, BANZAI.³ Therefore, we use those frames and conduct aperture photometry, and time stamp generation, as described above.

In the following analysis, we bin all data to the equivalent of a 20-s exposure time to ensure that all data points have the same weight.

3.2.1 Rotation signature

To analyse the low-frequency rotation signature, we perform differential photometry to remove the seeing, airmass, and transparency effects. The comparison star is ~ 105 arcsec from the target star with a magnitude of $V = 13.1$. Colour indices imply this star to be a late G or early K star, hence it may also show signatures of rotational variability. However, as we know details of the rotation period of J1640 from WASP data, this possible contamination is not an issue.

As with the WASP data, we calculate a Fourier transform in the frequency range $0 - 1 \text{ d}^{-1}$ and find the dominant frequency to be $0.272130 \pm 0.000006 \text{ d}^{-1}$, corresponding to a period of $3.67471 \pm 0.00008 \text{ d}$. As before, we increase our errors to provide more realistic errors in the presence of correlated noise, in this case by a factor of 5.95, providing a rotation period of $3.6747 \pm 0.0005 \text{ d}$. This value is in agreement with the WASP value, an expected result due to the long term stability of spots on Ap stars.

The amplitude of modulation in the B observations is much larger than in the WASP data, at 19.96 mmag, but even with this greater signal to noise, we do not detect any harmonics of the rotation period. A phase folded light curve with this result is shown in Fig. 5. Note that the amplitude varies in antiphase with the WASP data. An antiphase variation is often seen in Ap stars, though with observations in the visual and ultraviolet. It is thought that flux redistributed from rare-earth element line-blanketing causes this effect between the two passbands (Molnar 1973). However, it is less common to see variations between B and V (or the broad-band WASP filter) (e.g. Kurtz et al. 1996a; Drury et al. 2017; Gröbel et al. 2017), which indicates a null wavelength in the visual part of the spectrum (Molnar 1975).

3.2.2 Pulsation signature

We use non-differential photometry to analyse the pulsation in J1640 as this provides us with more precise data to work with, having avoided combining photon statistical observational errors of the comparison star with those of the target star when calculating the differential magnitudes. We fit and remove the airmass effects and other low-frequency variability, such as the rotation, in the range $0 - 10 \text{ d}^{-1}$ to the noise level at high frequency. Using non-differential photometry, however, does mean the loss of some data on non-photometric nights. After removing obvious outlying points (and those affected by cloud), and binning the data to 20 s integrations, the following analysis is conducted using 25 302 data points. The full light curve used for the pulsation analysis is shown in Fig. 6.

We calculate an amplitude spectrum of the full data set which is shown in Fig. 7; the pulsation frequency is clearly evident. Fig. 8 shows a zoom of the pulsation frequency (top panel), and subsequent pre-whitening steps of the pulsation and sidelobes. After identifying and extracting the pulsation frequency, we extract the sidelobes in pairs by identifying the dominant peaks around their expected position. This was an obvious procedure for the $\pm 1\nu_{\text{rot}}$ pair (as shown in the second panel of Fig. 8), but a more challenging task for the $\pm 2\nu_{\text{rot}}$ pair (shown in the third panel of Fig. 8). The presence of the sidelobes, split by the previously derived rotation frequency, within the errors, enables us to confirm that we have calculated the correct rotation frequency of the star, i.e. we have identified the true rotation period in Section 3.2.1 and not a harmonic of it.

We fit the pulsation signature in the light curve with non-linear least squares, and show the results in Table 4. The presence of the sidelobes in the Fourier transform imply that J1640 is a quadrupole pulsator like J1940 (Holdsworth et al. 2018), or a distorted dipole pulsator similar to HD 6532 (Kurtz et al. 1996b). Given that the shape of the quintuplet is very different from that of the distorted dipole seen in HD 6532, and similar to that of the distorted quadrupole of J1940, we deduce that J1640 is pulsating in a quadrupole mode. This deduction is supported by our models of the pulsation, as will be seen later in Section 4.

After fitting and removing the quintuplet, we search for further, previously undetected, pulsation modes. However, we find none at the level of 0.4 mmag, implying J1640 pulsates in a single mode. Although we do not detect further pulsations, the harmonics of the pulsation, up to and including 3ν , are present in the data (although only 2ν is visible at the scale of Fig. 7). The extracted harmonics are shown in Table 5. This is a common trait of the roAp stars and shows that the pulsations in these stars are non-sinusoidal, i.e. the pulsations are non-linear. The physical cause of this non-linearity in such low-amplitude pulsators is still unknown.

As previously stated, the pulsations in roAp stars can be represented using the oblique pulsator model. The model predicts the existence of sidelobes to the main pulsation frequency which are split by an exact frequency – the rotation frequency. We test this model for J1640 by forcing the frequency of the sidelobes to be exactly split by the rotation frequency, and then fit the data with linear least squares. When performing the fit, we select an appropriate zero-point to make the phases of the first sidelobes to be equal. Table 6 shows the result of the test. If the pulsation were a pure quadrupole mode, described by a single spherical harmonic, the quintuplet phases should be equal.

The phases derived from the least-squares fit are almost equal, however the average separation of the central peak and the first sidelobes are greater than 8σ . This result confirms our conclusion

that J1640 is pulsating in a distorted mode, and will be addressed in detail in Section 3.4.

3.3 Testing amplitude and phase variability

The stability of pulsations in roAp stars has been a topic for discussion since long-term, high-precision observations have been available; some of the stars show very stable pulsations while others show significant variability. HR 3831 is a prime example of how a time base of 16 yr allowed Kurtz et al. (1994a, 1997) to discuss significant frequency variability. More recently, high photometric precision has allowed the for the identification of phase/frequency changes in roAp stars observed by the *Kepler* space telescope (e.g. Holdsworth et al. 2014b; Smalley et al. 2015).

Furthermore, the recent analysis of quadrupole roAp pulsators has found them *all* to show unexpected pulsational phase variations (Balona et al. 2011; Holdsworth et al. 2014b, 2016, 2018). For a

pure quadrupole mode, the oblique pulsator model predicts a phase reversal as a pulsation node crosses the line of sight. However, this has not been the case for these pulsators, as shown in fig. 14 of Holdsworth et al. (2018). In these cases, it has been concluded that the stars, which have been modelled in detail, are pulsating with distorted modes (for a theoretical discussion, see e.g. Shibahashi & Takata 1993).

With this in mind, we test whether J1640 also shows unexpected frequency/phase variations over its rotation period, when compared to the theory for a pure normal mode. The amplitude and phase are calculated, at fixed frequency, in short sections of the light curve. These sections consist of 20 pulsation cycles, i.e. are about 0.13 d in length, dictated by a trade off between rotation phase coverage and frequency resolution. Fig. 9 shows the results of this test.

Considering a pure quadrupole pulsator, where the line of sight crosses one node, we expect the amplitude to be modulated to zero twice per rotation, and the phase to change by π rad. In the case of J1640, Fig. 9 shows this does not happen. The amplitude variations seen in J1640 are reminiscent of those seen in the roAp star α Cir, which is thought to pulsate in a dipole mode. In that case, as the star rotates, only one pulsation pole is seen resulting in a smooth sinusoidal variation. The smooth variation in the pulsation amplitude is a result of the change in viewing aspect of the one pulsation pole (Kurtz et al. 1994b; Bruntt et al. 2009). This casts doubt over our earlier deduction that J1640 is pulsating with a quadrupole mode.

However, in the case of α Cir, the phase is also constant, as one would expect when only observing one pulsation pole. This is not what is seen here with J1640. Between approximate rotation phases of 0.3 and 0.7, there is a small bump in the pulsation phase, as shown in the bottom panel of Fig. 9 (the solid line in the plot is to guide the eye to the small phase variation only), but this is still not the expected π rad change.

It is known that the rotational variation in the star's brightness generates apparent pulsation amplitude variations (Kurtz 1982). Because of this, the pulsation amplitude will be modulated in proportion to the overall light variations. In this case, our pulsation, at 5.8 mmag, combined with the rotation variation at 19.96 mmag, will produce two rotational sidelobes of the order 0.06 mmag. This is the same order as our error bars on the amplitude measurements, and much below the detected sidelobe amplitudes, implying that the rotational light variations cannot explain the presence of the observed sidelobes.

Along with the pulsation amplitude variations, we must also consider the effect of surface brightness inhomogeneities on the

Figure 8. Zoomed plot of the pulsation and rotational sidelobes, identifying the consecutive pre-whitening of the peaks, and the amplitude spectrum of the residuals (bottom). The vertical bars indicate the expected positions of the $\pm\nu_{\text{rot}}$ and $\pm 2\nu_{\text{rot}}$ sidelobes. The $+2\nu_{\text{rot}}$ peak is clearly present, however, the $-2\nu_{\text{rot}}$ peak is in the noise. Note the change in amplitude scale between the top and subsequent panels.

Table 4. Non-linear least-squares fit results to the full light curve. The frequency difference between one line and the previous is shown in the last column. The zero-point is BJD-245 7753.33141. Although at low amplitude, the $\nu - 2\nu_{\text{rot}}$ sidelobe has a 2.6σ significance, thus we believe it to be real.

ID	Frequency (d^{-1})	Amplitude (mmag)	Phase (rad)	Frequency difference (d^{-1})
$\nu - 2\nu_{\text{rot}}$	$151.398\,19 \pm 0.000\,59$	0.17 ± 0.06	-0.500 ± 0.631

$\nu + 2\nu_{\text{rot}}$	152.478 89	0.48 ± 0.06	1.082 ± 0.126

pulsation phase, as we also test this aspect of the pulsation. As stated, for a pure quadrupole mode, the observational pulsation phase jumps by π rad if the difference between the integrated amplitude of the positive and negative components of the pulsation changes sign, i.e. at a certain rotational phase when the line of sight crosses a node; otherwise the observed pulsation phase stays constant. However, for a distorted quadrupole mode, the pulsation phase changes gradually as the ratio of the contribution of the $\ell = 2$ components to the $\ell = 0$ component of the amplitude changes. The presence of spots would therefore modify the ratio and hence the observational pulsation phase proportionally. For J1640, as the spots affect the pulsation amplitude by ~ 1 per cent, we expect comparable effects in the observed pulsation phase, i.e. much smaller than the change we observe.

This almost-constant pulsation phase is similar to some other roAp stars: KIC 10483436 (Balona et al. 2011), KIC 7582608 (Holdsworth et al. 2014b), HD 24355 (Holdsworth et al. 2016), and J1940 (Holdsworth et al. 2018). It was found that all of these stars are quadrupole pulsators pulsating with distorted modes. Given the observed phase variation, and its similarity to the other quadrupole

Figure 9. Top: pulsation amplitude variation with rotation phase. Bottom: variation of the pulsation phase over the rotation phase. The solid line is to guide the reader in noticing the slight phase change between about 0.3 and 0.7 in rotation phase.

roAp pulsators, we model J1640 in Section 4 to further understand the distortion of the mode.

3.4 Mode geometry constraints

Due to the misalignment of the pulsation axis and rotation axis in the roAp stars, we are able to constrain the geometry of the pulsation modes in these stars. The method of Kurtz, Shibahashi & Goode (1990) allows us to estimate the angle of obliquity between the rotation and the pulsation axes, β , and the inclination angle of the star, i through comparing the amplitude of the rotational sidelobes. In the simplified case where the frequency quintuplet is caused by an axisymmetric, non-distorted (which it is not), quadrupole pulsation, and neglecting limb darkening effects, the following relation can be applied:

$$\tan i \tan \beta = 4 \frac{A_{-2}^{(2)} + A_{+2}^{(2)}}{A_{-1}^{(2)} + A_{+1}^{(2)}}, \quad (2)$$

where i and β are as above, $A_{\pm 1}^{(2)}$ are the amplitudes of the first sidelobes, and $A_{\pm 2}^{(2)}$ are the amplitudes of the second sidelobes.

Using equation (2) and values from Table 6, we calculate $\tan i \tan \beta = 0.97 \pm 0.16$ for this simple model; given our stated assumptions this value provides a first indication of the geometry of the mode. Due to the low resolution of the spectra presented in Section 2, we cannot determine $v \sin i$ and thus we are unable to disentangle i and β from the result of equation (2). However, when we model the pulsation mode in Section 4, we find that values of $i = 70^\circ$ and $\beta = 13^\circ$ best fit the observations, resulting in $\tan i \tan \beta = 0.634$. Comparing the value of $\tan i \tan \beta$ from equation (2), and the value derived using the model parameters, we can see that the simplified, non-distorted assumption is not correct.

Under the assumption that the spots causing the rotational light variations are at the magnetic poles, and that both poles have spots (which may not be the case, although is common in Ap stars), then from the single-wave rotational light variations we conclude that $i + \beta < 90^\circ$, since we see only one magnetic pole. If spots at both poles were seen, we would see a double wave rotational light variation.

Further to this, in the case of a non-distorted quadrupole mode, a node would not pass over the line of sight if either i and β are near to 90° , and we would see no phase variation of the pulsation.

Therefore, for a non-distorted mode, $i - \beta$ must be less than 54.7° for phase variations to be observed – the co-latitude of nodes for a pure quadrupole pulsator (as given by the Legendre polynomial: $P_2^0(\cos \theta) = \frac{1}{2}[3 \cos^2 \theta - 1]$).

However, in the case of the model parameters, i.e. $(i, \beta) = (70^\circ, 13^\circ)$, $i - \beta = 57.0^\circ$. This geometry would not cause a node to cross the line of sight in a non-distorted mode, and would then result in no pulsational phase variation. This is similar to what we show in Fig. 9, however with a small change detected in the observations, indicating a distorted mode, as we have previously shown.

4 MODELLING THE PULSATIONAL AMPLITUDE AND PHASE VARIATIONS

As previously stated, the oblique pulsations in roAp stars cause amplitude and phase modulations of the pulsation mode, which manifests itself as rotational sidelobes in the amplitude spectrum. When the geometry allows, the pulsation phase changes by about π rad when a node crosses the line of sight, i.e. the phase changes at amplitude minima. Nevertheless, this is not the case for J1640.

As previously discussed, the presence of a frequency quintuplet in the amplitude spectrum of J1640 is not conclusive evidence that the star pulsates in a quadrupole mode, given, for example the four sidelobes of the distorted dipole pulsator HD 6532. Furthermore, the smooth amplitude variation in J1640 is similar to that seen in α Cir, also a dipole pulsator. However, given the disparity between the sidelobe phases, and the small phase variation over the rotation period of the star, we do deduce it to be pulsating in a distorted mode.

We attempt to model this distorted pulsation by following the method of Saio (2005), as previously applied to model both J1940 (Holdsworth et al. 2018) and HD 24355 (Holdsworth et al. 2016). In short, we numerically solve the eigenvalue problem for non-adiabatic linear pulsations under a dipole magnetic field, with consideration of limb darkening for the Eddington grey atmosphere, i.e. $\mu = 0.6$, which is common practice for roAp stars (e.g. Ryabchikova et al. 1997). We expand the eigenfunction as a sum of terms proportional to Y_ℓ^0 with $\ell = 0, 2, 4, \dots, 38$. We refer the reader to those three papers for more detail. Here, we test both the distorted dipole and distorted quadrupole scenarios, due to our uncertainty of the mode type.

Fig. 10 shows the best dipole (left) and quadrupole (right) cases for where the model best replicates the amplitude and phase modulations observed in J1640. In both cases, the amplitude modulations can be reproduced well. However, in the case of the dipole model, there are no instances we can find where, when the amplitude modulation is well reproduced, the phase variations can be modelled.

This is not the case for the distorted quadrupole model. We are able to reproduce the phase modulations simultaneously with the amplitude modulations. Therefore, we conclude that J1640 is *most probably* pulsating in a distorted quadrupole mode. In this case, we find the following stellar parameters are required: $M = 2.0 M_\odot$, $\log L/L_\odot = 1.30$ and a polar magnetic field strength of $B_p = 1.70$ kG.

Here, we find that the amplitude and phase modulations are produced mainly due to a combination between the spherical symmetric component ($\ell = 0$) and quadrupole component ($\ell = 2$), where the energy contributed by the $\ell = 0$ and $\ell = 2$ components is almost equal. The small increase in pulsation phase during rotation phase between about 0.3 and 0.7 is mainly caused by the contribution of the $\ell = 2$ component, which has maximum visibility between these

Figure 10. Comparison of observed amplitude and phase modulations for the two models of J1640. Red lines/dots represent the observations, with black representing the models. Left: comparison of a distorted dipole model with the data. Right: comparison of a distorted quadrupole model with the data. In each column, the top panel shows a comparison of the quintuplet, with the observations shifted towards the right for clarity. The middle panel shows the amplitude modulations as a function of rotation phase. In each case, the best-fitting theoretical distorted model is represented by the solid line, the dotted line is the expected amplitude modulation from a pure mode, i.e. neglecting magnetic effects. The bottom panel shows the pulsation phase variations over the rotation cycle.

rotation phases and an opposite pulsation phase from the $\ell = 0$ component, with a small contribution from the $\ell > 2$ components.

5 DISCUSSION

To put our results into the context of other roAp stars which are pulsating in a distorted quadrupole mode, we make comparisons between KIC 7582608 (Holdsworth et al. 2014b), HD 24355 (Holdsworth et al. 2016), and J1940 (Holdsworth et al. 2018). We present a visual comparison of the four stars in Fig. 11. We have ordered the stars, top to bottom, by the increasing contribution of the $\ell > 2$ components of the spherical harmonic fit to the data. The solid lines on the figure represent the best-fitting model for each star, with the parameters shown in Table 7, alongside the measured frequencies and amplitudes of their respective pulsations. The amplitudes for J1640 and J1940 are the measured B amplitudes. The amplitude for HD 24355 is converted from the *Kepler* passband, Kp, to B band using the relation derived by Holdsworth et al. (2016), where simultaneous observations of the same star were made. The amplitude for KIC 7582608 is converted from the measured super-Nyquist amplitude in *Kepler* Long Cadence data to an undiluted amplitude using equation (1) of Murphy (2012) (due to severe under sampling of the pulsation), and then to a B amplitude using the same method as for HD 24355. The amplitudes presented in Table 7 are those used to normalize the amplitudes shown in Fig. 11.

As can be seen, there is a gradual change in the strength of the phase variations in these stars, from top to bottom. When comparing the contribution of the different spherical harmonic components of the fits, we find that more energy is being distributed to higher order terms. Most of the energy in J1640 is confined to the $\ell = 0$ and $\ell = 2$ components. This is almost the case for KIC 7582608 and HD 24355 too, however to reproduce the phase variations well,

higher ℓ terms are required. Finally, the energy of the $\ell = 0$ and $\ell = 2$ components for J1940 is not sufficient to describe the phase variation, and we find significant energy is contributed from the higher order terms. We show the relative kinetic energy of each of the $\ell = 0, 2, 4, 6$ components of each of the stars in Table 8.

There is a relation then between strength of the $\ell = 0$ and $\ell = 2$ components and the energy supplied by higher order terms, and the strength of the phase variation at rotation phase 0.5. We note here that the strength of the amplitude variations is much less dependant on the components of the spherical harmonic fit, but rather by the values of i and β i.e. changing the viewing aspect of the mode.

It is interesting to note that all four of these stars are extremely high-amplitude pulsators for roAp stars. Whether, then, these distorted quadrupole modes are only present in the highest amplitude roAp stars, or whether we are being subjected to a detection bias, is yet to be seen.

Furthermore, when comparing the characteristics of these four stars, we find they all show (within the limit of our observations) single pulsation modes which are above the theoretical acoustic cut-off frequency with pulsation phase changes much smaller than predicted. To put some of these characteristics into perspective, we plot these stars (in red) in the $T_{\text{eff}} - \nu L/M$ plane, after Saio (2014), in Fig. 12 alongside other roAp stars. It is obvious from the plot that these four stars occupy a region of this plane removed from all but one of the other roAp stars; due to the low amplitude signal in the pulsation spectrum of HD 42659 (Martinez & Kurtz 1994), it has yet to be studied in detail to determine if it is also a distorted quadrupole pulsator.

To construct Fig. 12, we used the effective temperatures presented in table 1 of Smalley et al. (2015), and, where available, *Gaia* parallaxes (from DR1) to estimate stellar luminosity (Gaia Collaboration et al. 2016a,b). In the cases where *Gaia* parallaxes are not

Figure 11. Comparison of amplitude and phase modulations of four quadrupole roAp stars, which pulsate in distorted modes. The stars are ordered, from top to bottom, in the increasing contribution of the higher order ℓ components of the pulsation. The strength of the phase change becomes more apparent from top to bottom. The data are plotted in red points, with the black line representing the model fits. The amplitudes are normalized to each star's maximum amplitude.

Table 7. Comparison of the model parameters used to calculate the fits to the phases and amplitudes of the four stars shown in Fig. 11; the values of i and β are interchangeable with each other. The final two columns are the measured parameters. The quoted pulsation amplitude is the peak-to-peak amplitude at pulsation maximum. The calculation of the B amplitude for KIC 7582608 and HD 24355 is discussed in the text.

Star	Mass (M_{\odot})	$\log g$ (cm s^{-2})	T_{eff} (K)	B_p (kG)	$\log L/L_{\odot}$	i ($^{\circ}$)	β ($^{\circ}$)	Pulsation frequency (d^{-1})	Pulsation amplitude (B) (mmag)
J1640	2.00	3.940	7700	1.70	1.298	70	13	151.934 63	20.68
HD 24355	2.00	4.051	8100	1.40	1.279	45	77	224.304 30	17.73
KIC 7582608	2.10	4.087	8570	4.00	1.357	75	25	181.737 39	26.40
J1940	2.00	3.914	7600	1.55	1.301	30	84	176.383 12	34.30

Table 8. The relative kinetic energy of the $\ell = 0, 2, 4, 6$ components for the four stars presented in Fig. 11, given the model parameters in Table 7.

Star	Relative kinetic energy			
	$\ell = 0$	$\ell = 2$	$\ell = 4$	$\ell = 6$
J1640	0.930	1.000	0.102	0.017
HD 24355	0.723	1.000	0.109	0.040
KIC 7582608	1.000	0.795	0.089	0.072
J1940	0.619	1.000	0.391	0.220

available, we use the $\log L/L_{\odot}$ given in Smalley et al. (2015). Where required, the bolometric scale of Flower (1996) was used. To determine the stellar mass, we compare the star's position with evolutionary tracks on the HR diagram. The tracks were produced with the MESA code (Paxton et al. 2013) with initial mass fractions

of hydrogen and helium of $X = 0.70$ and $Y = 0.28$, respectively. The full parameters used for the plot are given in Table A1. Not all roAp stars have this information available; that is why not all 61 roAp stars are plotted. The mass, luminosity and principal frequency parameters are combined to provide the $\nu L/M$ parameter; this eliminates the mass dependence of the cut-off frequency and instability range due to H-ionization zone at a given effective temperature.

The positions, in Fig. 12, of the four stars discussed here have been determined with the model fits, i.e. using the parameters in Table 7. However, we note that there is a *Gaia* parallax (from DR1) of HD 24355 which places the star below the zero-age main sequence, which is contradictory to the values derived from spectroscopy and pulsation modelling (Holdsworth et al. 2016). We therefore adopt the model luminosity, and await a second data release for more accurate measurements of the parallax.

Figure 12. The positions of roAp stars in the $T_{\text{eff}}-\nu L/M$ plane, in which L/M is in solar units. The principal frequencies are represented by squares, with vertical bars showing the range of frequencies for multiperiodic stars. The hatched region is where the κ -mechanism excites high-order p-modes in the H-ionization zone in non-magnetic models. Acoustic cut-off frequencies are represented by the dashed lines. The red squares of J1640, J1940, HD 24355, and KIC 7582608 are stars that have been studied in detail and show similar characteristics which differ from the other stars. The numerical labels correspond to the stars in Table A1. Figure adapted from Saio (2014).

This discrepancy between the *Gaia* derived luminosity and that from spectroscopy and pulsation modelling may be present in some of the other black points in Fig. 12. We do not yet have a uniform data set to construct the diagram, and so caution must be exercised when drawing conclusions. Further releases of *Gaia* data, especially of the four red points, will provide better constraints on the luminosity. Furthermore, light curves obtained by the *Transiting Exoplanet Survey Satellite* (*TESS*) mission (Ricker et al. 2015) will provide us ample data to model the pulsations in the roAp stars. These two data sets will provide a nearly homogeneous data set to work with, thus removing many of the biases currently present in the data used to plot Fig. 12.

The identification and study of J1640 as only the fourth member of these strongly distorted pulsators is allowing us to test the extremes of the pulsations seen in the roAp stars. Previous studies of ‘well behaved’, non-distorted, quadrupole pulsators have not allowed for the testing of the pulsation models, in the context of the contribution of high order ℓ components, to the extent we are able to do here.

The seemingly related subgroup of roAp stars is allowing us to test the pulsation theory which has, so far, well represented the pulsations in most of the members of this class. Although we are able to force our current models to fit these extreme members of the roAp stars, perhaps their supercritical, phase-suppressed pulsations require an entirely different pulsation driving mechanism. This may come in the form of turbulent pressure driving the pulsation, as suggested by Cunha et al. (2013), but further examples and comparisons are needed to confirm this.

6 SUMMARY AND CONCLUSIONS

The identification of J1640 as a roAp star through a search of the SuperWASP photometric archive provided an indication that it is one of the highest amplitude roAp stars known to date, when considering the change in measured pulsation amplitude as a function of wavelength (Medupe & Kurtz 1998). We have presented an analysis of the WASP data in more detail than presented in the discovery paper (Holdsworth et al. 2014a). Furthermore, we have presented the analysis of multisite photometric data targeting J1640 made with *B* observations. The results show that, as expected, J1640 is one of the largest amplitude roAp pulsators.

J1640 was observed as a secondary target in the 2016 observing season at the South African Astronomical Observatory. It was clear from these observations that J1640 warranted its own dedicated follow-up. To that end, we observed the star in the 2017 season for a total of 199 h with the 1.0-m telescope at SAAO and the Las Cumbres Observatory 1.0-m telescope network located at both the Siding Springs Observatory in Australia, and the Cerro Tololo Interamerican Observatory in Chile. The longitudinal separation of the telescopes allowed for almost continuous observations (for a limited time).

The best measure of the rotation period of J1640 comes from the analysis of the follow-up observations with a *B* filter. The increased amplitude of the rotation signature over the WASP data allowed us to more precisely determine the period, despite the shorter time base of observations. Assuming that the spot(s) which cause the mean light variations are stable, and assuming the oblique rotator model of Stibbs (1950), we find a period of 3.6747 ± 0.0005 d. This is also in agreement with the period found from the WASP data.

Analysis of the final light curve revealed that J1640 pulsates with a single mode with a central frequency, surrounded by four sidelobes split by one and two times the rotation frequency. Such a manifestation is a result of oblique pulsation of a quadrupole mode. The outermost sidelobes, however, have low amplitude, and the two inner most sidelobes are out of phase with the other peaks, leading to the conclusion that the quadrupole mode in this star is distorted.

The full light curve provides us with almost complete rotation-phase coverage of the star. As a result, we have been able to analyse the pulsation amplitude and phase as the star rotates. We find that the amplitude varies in a sinusoidal way, but the phase is almost constant – contrary to what would be expected for a non-distorted mode. To investigate this phenomenon further, we model J1640 using the method of Saio (2005). The modelling results confirm that J1640 is a quadrupole pulsator, with a magnetic field of strength 1.70 kG distorting the mode.

Furthermore, when considering the components of the spherical harmonic series which describes the pulsation in J1640, we find that the mode is dominated by the $\ell = 0$ and $\ell = 2$ components, with small contributions from the higher ℓ terms.

The amplitude and phase variations in J1640 are reminiscent of those seen in KIC 7582608 (Holdsworth et al. 2014b), HD 24355 (Holdsworth et al. 2016), and J1940 (Holdsworth et al. 2018). They too are quadrupole pulsators with suppressed phase variations. In modelling those stars in the same way as we have presented here, we find there is a dependence on the strength of the high order ℓ components of the pulsation on the strength of the phase variability. The greater the phase variation, the stronger the $\ell > 2$ components are. These stars all pulsate with very high amplitudes, when compared to the roAp class of stars as whole. This leads us to question whether the extreme distortions are linked to the amplitude of pulsation, or

whether we are currently only able to detect this phenomenon due to observational limits.

We will be afforded the opportunity to conduct a homogeneous study of (most of) the roAp stars with the launch of the *TESS* mission. At the expected precision of *TESS*, we will be able to identify *all* the distorted quadrupole (and dipole) pulsators, allowing us to test the significance of the spherical harmonic components of a large sample of stars, and to determine if the pulsation amplitude plays a significant role in the distorted stars. Until then, we will continue to study these stars with ground-based observations.
